#### <span id="page-1-0"></span>Introduction and motivations

An interesting approach to understand confinement is to compactify the theory on a  $R^3 \times S$  manifold. The compactification radius sets the energy scale of the theory and the hope is, by squeezing the radius, to reach a weak coupling regime where perturbative methods can be used.

**•** The main problem in this direction is that at some critical value  $N_{t,c}$  of the compactification radius  $N_t$ , the model undergoes a deconfinement transition.

 $\Omega$ 

 $4$  O  $\rightarrow$   $4$   $\overline{m}$   $\rightarrow$   $4$   $\overline{m}$   $\rightarrow$   $4$ 

#### Introduction and motivations

• A recent interesting proposal to avoid this problem is to add to the action a "trace deformation" so as to keep the model in the confined phase $^1$ .

$$
S^{\rm def} = S_{\rm YM} + h \int |{\rm Tr} P(\vec x)|^2 {\rm d}^3 x\ ,
$$

- The question is thus if this "reconfined" phase of the model shares the same properties with the original confining phase.
- Some properties seem to be conserved: the glueball spectrum, the localization/delocalizations transition of the Dirac eigenvalues the  $\theta$  dependence of the free energy....
- Some other properties, like the monopole condensation seem to show a different behaviour.
- However the definitive test of similarity is on the behaviour of the confining flux tube.

 $\Omega$ 

The model:  $(2+1)$   $SU(2)$  in the reconfined phase.

$$
S^{\text{def}} = S_{\text{W}} + h \sum_{\vec{x}} |P(\vec{x})|^2 ,
$$

where  $S_{\rm W}$  is the usual Wilson action

$$
\mathsf{S}_{\mathrm{W}} = -\frac{\beta}{2} \sum_{\mathsf{x}} \sum_{0 \leq \mu < \nu \leq 2} \mathsf{Tr} \ U_{\mu \nu}(\mathsf{x})
$$

and  $P(\vec{x})$  is the Polyakov loop defined as

$$
P\left(\vec{x}\right) = \text{Tr}\prod_{t=0}^{N_t} U_0\left(t, \vec{x}\right).
$$

We are interested in the two-point correlation function:

$$
G(R) = \left\langle \sum_{\vec{x}} P(\vec{x}) P(\vec{x} + R\hat{k}) \right\rangle,
$$

### The phase diagram.

At a fixed value of  $\beta$  and  $N_t$ , chosen so as to have the model in the deconfined phase if we increase  $h$  at some point we find a "reconfinement transition" which in all the models studied up to now is always of the first order.

This is the Finite Size Scaling analysis of the susceptibility for the  $SU(2)$  model in  $(2+1)$ dimensions with  $N_t = 10$  and  $\beta = 23.3805$  (for which the deconfinement transition is located at  $N_{t,c} = 15$ ) 4 ロ ト 4 伺 ト 4 ヨ つへへ

# <span id="page-6-0"></span> $(2+1)$   $SU(2)$  in the reconfined phase: data

So, to analyse the behaviour of the flux tube in the reconfined phase we select a set of values of  $\beta$ ,  $N_t$  and h beyond the reconfinement transition.

Table: Some information on the simulations.

We evaluate for each combination of  $\beta$ , h and  $N_t$  the Polyakov loop correlator for several values of  $R$  and extract the ground state energy of the flux tube.

#### <span id="page-7-0"></span>Effective String Theory

For a generic EST in  $D=2+1$ , we have $^2$  for  $R>>N_t$ 

$$
\langle P(0)P^{\dagger}(R)\rangle = \sum_{n=0}^{\infty} |v_n(N_t)|^2 \frac{E_n}{\pi} K_0(E_n R)
$$

 $\bullet$  In the large R limit the sum is dominated by the lowest state and from the exponential decay of the modified Bessel function thus we may fit the Polyakov loop correlators using

 $\langle P(0)P^{\dagger}(R)\rangle = A K_0(E_0(N_t)R)$ 

and extract from the fit the ground state energy  $E_0(N_t)$  we may extract the correlation length  $E_0(N_t)$ . This is true for any EST. If we want to characterize the particular EST which describes our LGT we must look at the the  $N_t$  dependence of  $E_0$  allows to distinguish between different effective strings For instance, for the Nambu-Goto string we have:

$$
\mathit{E}_{0}=\sigma\mathit{N}_{t}\sqrt{1-\frac{\pi}{3\sigma N_{t}^{2}}}
$$

### <span id="page-11-0"></span>The "rigid string"<sup>4</sup>

.

The "rigid string" is obtained adding to the Nambu-Goto action a term proportional to (square of) the extrinsic curvature which has the effect of increasing the "stiffness" of the string.

$$
S_R = \int_{\Sigma} d^2 \xi \sqrt{g} , \left[ \sigma + \alpha \mathcal{K}^2 + \dots \right] ,
$$

where K is the extrinsic curvature defined as  $\mathcal{K} = \Delta(g)X$ , with

$$
\Delta(g)=\frac{1}{\sqrt{(g)}}\partial_s[\sqrt{(g)}g^{ab}\partial_b]
$$

In the "physical gauge" in  $(2+1)$  dimensions, keeping only the first order terms this boils down to:

$$
S_R = \int_{\Sigma} d^2 \xi \ \sigma \ \partial X \partial X \ + \ \alpha \ \partial^2 X \partial^2 X \ + \ \ldots \,,
$$

#### <span id="page-12-0"></span>The "rigid string"

The standard approach to study the model was to treat the  $\mathcal{K}^2$  term as a perturbation of the gaussian one. Comparing the corrections obtained in this way with simulations it turned out that  $\alpha$  was compatible with zero for all ordinary non-abelian LGTs. In recent years it has been understood that this is due to the fact that the  $\mathcal{K}^2$  term can be eliminated since it is proportional to the eq. of motion of the NG string and that a better proposal to describe higher order perturbations to the Nambu-Goto action is instead

$$
S_{BNG} = \int_{\Sigma} d^2 \xi \sqrt{g} , \left[ \sigma + \gamma_3 \mathcal{K}^4 \dots \right] ,
$$

This is the origin of the deviations with respect to NG observed in  $SU(N)$  LGTs (see the talk by D. Panfalone)

 $QQ$ 

### <span id="page-13-0"></span>The Polchinski-Yang proposal

- A completely different approach to study  $S_R$  was proposed in 1992 by Polchinski and Yang which described the rigid string assuming the quartic term as the dominant one and the quadratic NG term as a small perturbation.
- This corresponds to a completely different vacuum and requires  $\alpha >> N^2_t \sigma$  and  $\mathsf{N}^2_t\sigma << 1$  and corresponds (apparently) to an unphysical regime since for **ordinary V<sub>t</sub>**  $\theta \leq 1$  and corresponds (apparently) to an unprivate regime since for **ordinary**<br>**YM theories**  $N_{t,c} \sim 1/\sqrt{\sigma}$ , thus if  $N_t^2 \sigma \ll 1$  the model is deconfined and thus we do not expect the presence of a confining flux tube and thus of an effective string description.
- Despite this, this regime was studied in great detail for completely different reasons. The goal was to show that in this particular regime the (unphysical) high temperature behaviour of model was the same of that of QCD in the large N limit.

 $4$  ロ }  $4$   $\overline{m}$  }  $4$   $\overline{m}$  }  $4$   $\overline{m}$  }

### <span id="page-14-0"></span>The Polchinski-Yang solution<sup>5</sup>

The Polchinski-Yang solution for generic values of the transverse dimensions is

 $E_0 = w\lambda$ 

where

$$
w = \sqrt{N_t^2 - \frac{(d-2)N_t}{2}} \sqrt{\frac{1}{2\alpha\lambda}}
$$

and

$$
\sqrt{\lambda} = \frac{3}{8} \frac{(d-2)}{N_t \sqrt{2\alpha}} + \sqrt{\frac{9}{128} \frac{(d-2)^2}{\alpha N_t^2} + \sigma - \frac{\pi(d-2)}{3N_t^2}}
$$

From this solution it is possible to obtain the new value of the deconfinement temperature, which is given by:

$$
\mathsf{N}_{t,c}^2\sigma=\frac{\pi(d-2)}{3}-\frac{(d-2)^2}{16\alpha}
$$

which, as expected, is higher than the standard one (which is  $\mathsf{N}^2_{t,c}\sigma = \pi(d-2)/3)$

## <span id="page-20-0"></span>Summary

- Most likely the reconfined flux tube is not of the Nambu-Goto type If this is the case, then understanding which are the physical degrees of freedom driving the formation of the confining flux tube in ordinary YM theories is still an open problem
- The presence of the rigidity term is directly related (by the Polyakov solution) to the condensation of monopoles, which is most likely the mechanism which drives confinement in the reconfined phase. This agrees with the original analysis of Unsal and Yaffe
- Deformed YM theories in the reconfined phase represent a lattice realization of the (apparently) unphysical solution of Polchinski and Yang
